Mucocutaneous Features of Zika—a Review

Xuan Qi Koh[1] · Nisha Suyien Chandran[2] · Paul Anantharajah Tambyah[3]

Published online: 30 April 2019

Abstract

Purpose of Review We review the range of dermatological signs seen in Zika infection and the possible relationship between the rash and viremia. We also hoped to explore the utility of mucocutaneous manifestations in narrowing the differential diagnosis from other similar flaviviruses.

Recent Findings Clinical manifestations of Zika infection share many similarities with other mosquito-borne viruses such as dengue. These include non-specific symptoms such as a fever, rash, arthralgia, myalgia, and conjunctivitis. The morphology of the rash in Zika infection is not very specific and commonly described as maculopapular and centrifugal that usually extends to become diffuse.

Summary We reviewed 123 publications, encompassing a total of 368 Zika cases. One hundred seven cases with rash had sufficient data for detailed analysis. 8.4% of cases with rash had hemorrhagic manifestations such as palatal petechiae and bleeding ulcers. Only 20 reported cases were tested for viremia during presence of rash, and 70.6% of these cases were positive. While mucocutaneous complications are common in Zika infection, more research is necessary to determine the impact of rash on diagnosis, prognosis, and transmissibility in Zika infection.

Keywords Zika · Exanthem · Conjunctivitis · Flavivirus · Arbovirus · Rash

Introduction and Background

The Zika virus is a mosquito-borne virus that was discovered in Africa in 1947 [1] with the first human infection in 1952 [2]. It has only come to global attention in the last decade for its neurologic and teratogenic complications. The virus is a *Flavivirus*, in the same family as dengue virus, West Nile virus, yellow fever virus, Japanese encephalitis virus, and tick-borne encephalitis virus. Interestingly, the flaviviruses tend to have certain clinical characteristics: dengue and yellow fever viruses result in more hemorrhagic manifestations, while West Nile virus and Japanese encephalitis virus cause more neurologic damage. The Zika virus falls more closely on the phylogenetic tree to dengue virus, with Zika and dengue sharing many clinical features [3]. It is also difficult to differentiate clinically and serologically from dengue.

The defining surveillance criteria for a suspect Zika case includes the presence of rash, fever, and conjunctivitis in an epidemiologically appropriate population. For example, in 2016, the Singapore Ministry of Health defined a possible Zika case as any person who had fever and rash, with at least another symptom of either headache, myalgia, arthralgia, or conjunctivitis, and a history of living, working, or studying in an outbreak area. These symptoms and signs are not specific to Zika infection, and are frequently present in other flavivirus infections. This review article aims to explore the following

clinical questions: what are the mucocutaneous signs and symptoms present in Zika infection, whether these signs correlate with viremia, and whether the timeframe in which these occur assist the clinician in managing Zika infection especially in patients at risk of other flaviviruses.

Two Different Lineages of Zika

The Zika virus is subdivided into two major lineages—African, and Asian. Although the Asian lineage is responsible for most of the recent outbreaks across the world in particular in the Americas (2012 to 2016), a phylogenetic study suggests that the divergence of the Asian lineage from the African lineage occurred approximately 180 years ago [4].

There is a paucity of data on the clinical features of infection by African lineage of Zika virus. There are, however, in vitro studies that suggest differences in virulence and pathogenicity between the two strains [5•]. The pattern of innate immune responses triggered by African and Asian Zika strains in the human dermal fibroblasts and epidermal keratinocytes is reportedly different [6•]. Whether these in vitro differences manifest as clinical differences between the Asian and African strains is currently unknown and difficult to explore given the very few published clinical reports of individuals infected by the African lineage of Zika virus.

Overview of Clinical Features of Zika

Zika virus infection can be asymptomatic in many and possibly the majority of cases. Reported clinical manifestations include fever, arthralgia, rash, pruritus, myalgia, conjunctivitis, diarrhea, retro-orbital pain, and headache. Rash is the commonest cutaneous sign, described as maculopapular starting from the trunk and spreading to the limbs and face. A review of 66 cases published up to December 2016 found that 59% of rashes were described as maculopapular, with 44% being pruritic. Bleeding manifestations such as purpura, gingival bleeding, and oral hemorrhagic blisters were also present [7••].

Conversely, cutaneous features are rare in the congenital Zika syndrome. The major features of congenital Zika syndrome include brain malformations and neurological signs such as hyper- or hypotonia. Jaundice, hepatosplenomegaly and ocular complications are also important signs [8].

Literature Review

A literature search on the United States National Library of Medicine's Pubmed database using "Zika" and limited to "Case reports," "Clinical study," "Meta-analysis," "Multicenter study," "Observational study," and "Randomized Controlled Trial" yielded a total of 267 publications between February 1976 and September 2018.

All English language case reports, case series, and cohort studies which provided accessible information on clinical features of Zika infection or congenital Zika syndrome, together with confirmation of Zika infection via either detection of Zika RNA or serology, were included. Publications that were not written in English were excluded from this review. Publications that could not be accessed or for which the abstracts did not provide sufficient information were also excluded. Thirdly, cases where the diagnosis was in doubt, or where there was more than one infection that could have contributed to the clinical signs as determined by one of the authors (XQK), were also excluded from this analysis.

For cases with a rash or conjunctivitis, available details about onset, duration, morphology, distribution, and associated itch were entered into the data collection sheet. The results for Zika polymerase chain reaction (PCR) tests and serology, where available, were also tabulated.

Results of Literature Review

Of the initial 267 publications, 123 publications fulfilled our inclusion criteria as stated above. The remaining 144 publications were excluded from this analysis as they were either unable to be accessed, written in a language other than English, not certain about the diagnosis of Zika, had confounding factors casting doubt on the cause of their clinical signs, had insufficient details regarding laboratory or clinical findings, or were irrelevant to this review.

Out of the 123 included publications, 10 publications were case series or cohort studies that reported the frequency of rash or conjunctivitis in their respective study populations, without further detail on individual cases. Seventeen publications reported neonatal cases where Zika infection was acquired prenatally or perinatally. The remaining 96 publications reported a total of 128 individual adult cases of Zika infection.

Cutaneous Features of Zika

For the 10 publications of case series or cohort studies which did not provide sufficient details for analysis of individual cases, a total of 216 out of 240 cases (90%) had rash. Comparably, 107 out of the 128 individual adult Zika case reports (83.6%) had a rash. 42.1% of these 107 individual cases described the rash as maculopapular, while another 12.2% of the 107 cases were described as erythematous macules or patches. 3/107 cases described the rash as an exanthem. Commonly affected distributions included the trunk, upper limbs, lower limbs, neck, and face. 6.5% of the 107 individual case rashes involved the palms and/or soles. 9/107 cases (8.4%) had hemorrhagic manifestations such as

petechiae, bleeding ulcers, ecchymoses, bleeding gums, and even spontaneous hematomas [9]. A middle-aged woman demonstrated a positive Rumpel-Leede sign, where linear petechiae were seen on her upper arm after a sphygmomanometer cuff had been inflated over it. The Rumpel-Leede sign has been observed in other flavivirus infections such as dengue and Chikungunya and is thought to be due to capillary fragility [10•].

The onset of rash was specified in 39 out of 107 individual adult Zika cases (Fig. 1). The earliest documented rash occurred on day 0 of symptoms, and the latest onset was on day 7. The median onset was on day 1, while the mean onset was day 2. The duration of rash was documented in 52 out of 107 individual adult Zika cases (Fig. 2). The shortest duration was 12 h [11], while the longest lasted up to 9 days [12]. The median duration was 5 days, and the average duration was 4.6 days. Not all cases which documented onset of rash gave the duration of rash, and vice versa.

The relationship between rash and viremia or viruria was not very clear. Of the reported 107/128 individual adult Zika cases who had a rash, only 20/107 cases were confirmed to have had Zika PCR of either whole blood, serum, urine, or saliva performed during the period of active rash. Cases without the onset or duration of rash documented could not be analyzed for this or if they were tested with Zika PCR outside the period of rash. 12/17 (70.59%) samples from serum or whole blood in patients with rash showed the presence of viremia. Thirteen of 20 cases were tested for urine Zika PCR during the rash; all were positive (100%). There were 2 cases that had negative serum but positive urine Zika PCR. Conversely, there were no cases with rash that had positive serum PCR but negative urine PCR. Although the numbers are small, this is consistent with other observations that urine PCR is more sensitive than serum PCR. Quantitative PCR titers were not reported.

Conjunctivitis in Zika

Compared to other flavivirus infections, conjunctivitis appears to be a more prominent feature of Zika virus infection. The presence of conjunctivitis was documented in 9 out of the 10 case series or cohort studies that did not have individual patient information. These yielded a total of 121 cases, of which 45 (37.19%) had conjunctivitis. This percentage is comparable to the frequency of conjunctivitis in the 128 individual adult Zika case reports where 47 patients (36.72%) had conjunctivitis. One patient had punctate keratitis and bilateral keratic precipitates requiring topical ciprofloxacin-dextromethorphan [13]. Ten of 47 cases specified the day of onset of conjunctivitis (Fig. 3); half demonstrated conjunctivitis on day 1. Nine out of the 10 cases had simultaneous onset of conjunctivitis with rash. The last case started to have conjunctivitis on day 2 and rash on day 3 of symptoms [14]. One case demonstrated conjunctivitis as late as day 10 of symptoms [15]. The median onset of conjunctivitis was day 1.5, and the mean was day 2.6. The duration of conjunctivitis was specified in 11 cases (Fig. 4): the shortest duration was 3 days, and the longest up to 11 days. The median duration was 5 days and the average duration 5.6 days.

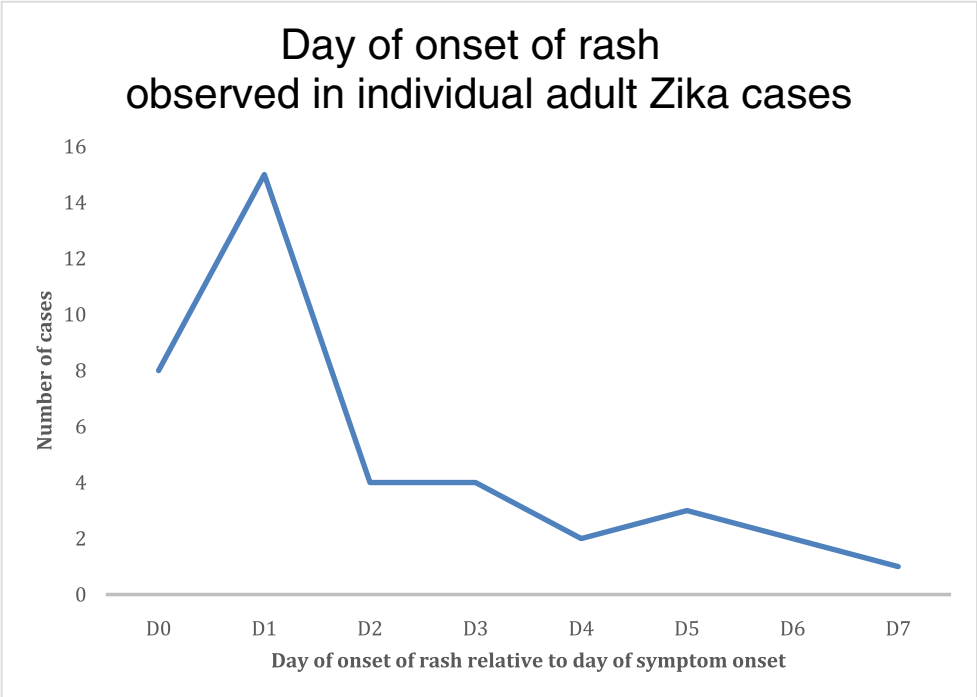

Fig. 1 The number of cases of rash observed in the individual adult Zika cases against the day of onset of rash relative to day of illness

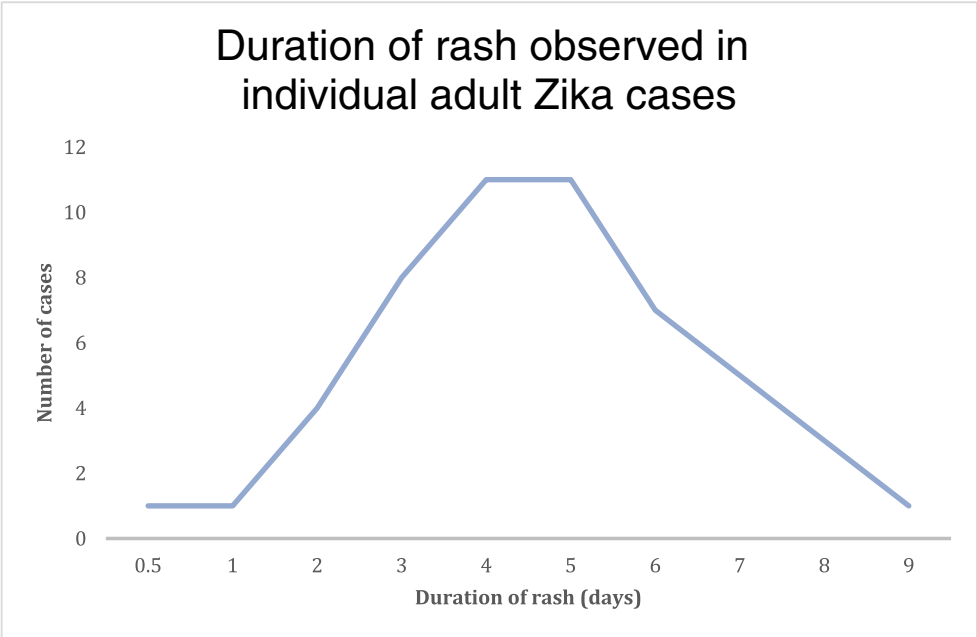

Fig. 2 The number of cases of rash observed in the individual adult Zika cases against the duration of rash in days

Zika PCR was performed in 5 cases while symptomatic with conjunctivitis. All 5 cases had positive urine Zika PCR (100%). four out of 5 cases were tested for viremia, with 1 out of 3 serum Zika PCR being positive, and 1 out of 1 whole-blood Zika PCR positive again reinforcing the better sensitivity of urine PCR for individuals with Zika virus infection.

Mucocutaneous Features in Neonates Born to Mothers Who Had Gestational or Perinatal Zika Infection

There were 17 publications on clinical neonatal Zika infections, whether acquired prenatally or perinatal. two of these publications were larger case series without individual case data about mucocutaneous features. Meneses et al. reported 87 cases of congenital Zika syndrome in which 71% of these cases were born with microcephaly, but did not report on the absence or presence of redundant scalp skin [16]. Van der Linden et al. reported 13 cases of congenital Zika syndrome in which 11/13 (84.61%) were diagnosed with postnatal microcephaly. 6/13 infants had craniofacial disproportion, and 3 of these infants had redundant scalp skin at birth. None of these 6 infants had microcephaly at birth, but it is not specified if they developed postnatal microcephaly later [17•].

In the remainder 15 publications, there were 20 individual neonatal cases of Zika acquired prenatally or perinatal. Sixteen of 20 individual case reports did not document the presence of any mucocutaneous features. Three of 20 had congenital Zika

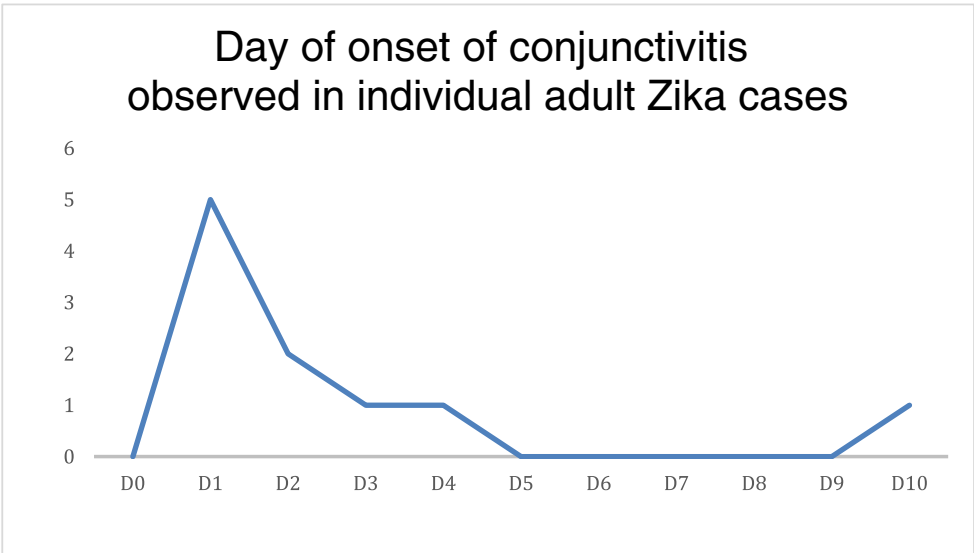

Fig. 3 The number of cases of conjunctivitis observed in the individual adult Zika cases against the day of onset of conjunctivitis relative to the day of symptom onset

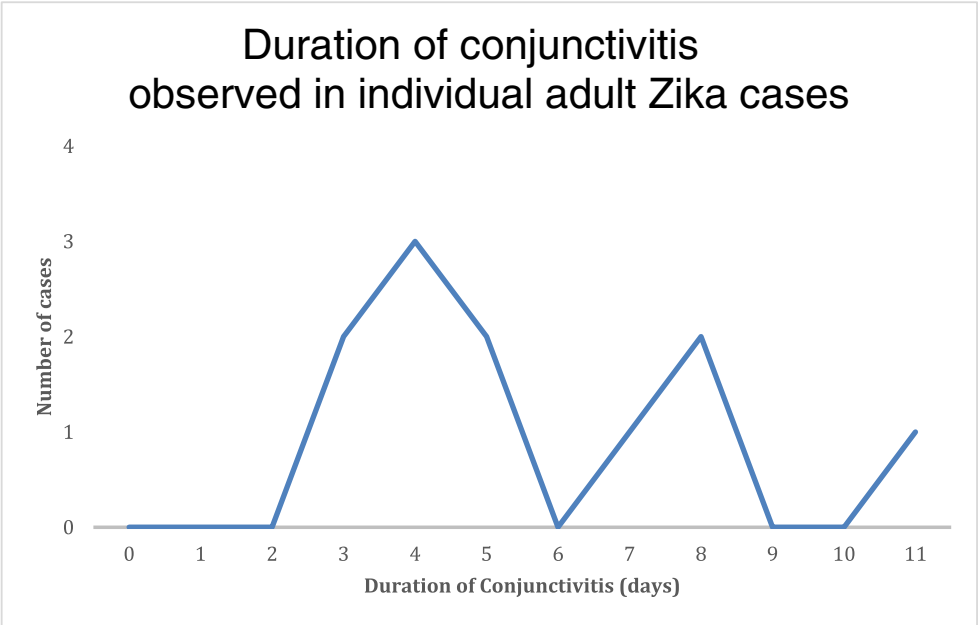

Fig. 4 The number of cases of conjunctivitis observed in the individual adult Zika cases against the duration of conjunctivitis in days

syndrome with severe microcephaly and redundant scalp skin at birth. One infant of the 20 presented with isolated diffuse rash on day 4 of life, likely having acquired Zika by breastfeeding. The neonate's mother had positive Zika PCR in her breastmilk, and neonatal serum Zika PCR was initially negative on day 3 of life, only becoming positive on day 4 at the onset of rash [18]. There were no neonates reported with conjunctivitis or other mucosal involvement.

Relationship Between Zika Viremia or Viruria and Rash

To determine the duration of viremia or viruria specifically in patients with rash, we evaluated information on serum, whole blood, and urine PCR results from the 107 individual adult Zika case reports; case series or cohort studies without raw data did not lend themselves to statistical analysis.

Out of 107 cases with rash, 77 cases had documented serum Zika PCR results. 49/77 cases had positive serum Zika PCR but 6 of these cases did not specify when the test was taken. 28/77 had negative first serum Zika PCR on first sampling. Table 1 demonstrates that most of the cases had their first positive serum Zika PCR taken in the first week of symptoms.

In contrast to this, Table 2 tabulates the first day of negative serum Zika PCR relative to day of illness. Forty-four of the 107 cases with rash had specified the day of first negative serum Zika PCR. The median time to a negative PCR was day 10.4 of illness, and mean is day 7.

We also compared serum to urine Zika PCR results. 46/107 cases had both serum and urine Zika PCR done. 17/46 cases had first positive sampling for both serum and urine PCR on the same day. 8/46 cases documented different first positive sampling dates for both serum and urine PCR—in 7 of these 8 cases, the first positive urine sample was taken at a later time compared to the first positive serum sample. One of the 8 cases had a positive serum Zika PCR with a negative concurrent urine Zika PCR [38]. 15/46 cases documented the dates when serum and urine Zika PCR became negative. In 10/15 cases, serum Zika PCR became negative before urine Zika PCR. In 5/15 cases, serum and urine Zika PCR were documented negative on the same day consistent with the observation that urine remained positive for Zika PCR longer than serum.

Whole-blood Zika PCR testing and saliva PCR were reported in a small number of cases of Zika with rash and thus are difficult to interpret in drawing conclusions about rash and viremia or salivary excretion of the virus.

Discussion

Zika is an emerging infectious disease with a newly recognized syndrome—the congenital zika syndrome with a significant impact on public health. Mucocutaneous manifestations are a prominent feature of Zika virus infections in both individual case reports and large published case series. While it is possible that the high frequency of rash occurring in acute Zika infection is a function of clinical case definitions adopted by the various public health agencies (WHO and CDC), our literature review suggests that rash is very common in Zika virus infection. The percentage of individual adult Zika cases from case reports who developed rash (83.6%) was similar to that of the pooled cases from the 10 publications of case series

Table 1 Patients with either rash, conjunctivitis, or both symptoms

or cohort studies (90%). The rash often developed within the first 2 days of illness and was unlikely to occur after the first week of symptoms. It lasted an average of 4.6 days. The rash most commonly manifested as maculopapular (42.1%), but could also include hemorrhagic signs (8.4%) (Fig. 5).

Possibly because of the inclusion of rash but not conjunctivitis in the case definition, there were fewer patients who had reported conjunctivitis compared to rash (37% versus 83.6–90%) in the published case reports. Patients tended to develop conjunctivitis early in the course of the disease (median of day 1.5), and this often coincided with the onset of rash. The duration of conjunctivitis was on average slightly longer than that of rash (4.6 versus 5.6 days). Due to the limitations of serial testing for Zika virus infection, it is not possible to determine the relationship between the duration of fever and/or conjunctivitis and infectivity. There are reports of persistence of Zika virus in conjunctival fluids for up to a month after the onset of infection raising the possibility that tears like other body fluids may be an important mode of transmission [106].

The diagnosis of Zika versus other flaviviruses is a challenging one. Chikungunya and dengue viruses are both flavivurses that are also transmitted by the *Aedes* spp. mosquito, and thus often endemic in the same geographic locations as Zika. Hanley et al. compared the common clinical and laboratory features of Zika with that of dengue infections in 2 prospective cohorts of patients in Singapore. In this study, there were 130 cases of Zika and 175 cases of dengue. It was found that the presence of both a rash and conjunctivitis within the first 5 days of symptom onset in a suspected case increased the probability of Zika infection by 35 to 44%, but had no effect on the post-test probability of dengue infection. Conversely, the absence of rash in the first 5 days of symptomatic illness decreased the

Table 2 Studies in which rash or conjunctivitis was measured as an outcome

Study	Purpose of study	Primary outcomes of study	Related outcomes to our study	Number of patients	Frequency of rash	Frequency of conjunctivitis
García-Bujalance et al. (2017) [27]	To investigate the persistence and infectivity of Zika virus in semen	Semen Zika PCR was detected from days 14–96 since onset of illness.	4 out of 5 infected men had rash. 3 out of 4 men with rash had a positive semen viral culture for Zika. 2 out of 4 men with rash had positive urine Zika PCR. All men, including the asymptomatic man, had positive semen Zika PCR.	5	0.80	0.00
Passos et al. (2017) [97]	To investigate whether co-circulation of Zika with dengue could have occurred before the reported cases in 2015	Frozen semen samples collected during an outbreak in 2013, which tested negative for dengue, were tested for Zika PCR and there were positive results. This suggests that Zika virus was already circulating in Brazil in 2013.	3 out of 210 samples collected during dengue outbreak were both negative for dengue and positive for Zika. A retrospective review of their symptoms revealed that none of them had exanthema, and only 1 of the 3 cases had eye redness.	3	0	0.33
Joguet et al. (2017) [98•]	To investigate the effects of Zika infection on semen and how long Zika virus persists in semen and body fluids	There was an increase in abnormal sperm and decrease in total sperm count at day 30 post symptom onset. Recovery was observed between days 90–120. Whole-blood Zika PCR remained positive up to day 120 for 3 patients in this study.	Serum and urine Zika PCR were positive in all patients by day 7 post symptom onset. Serum Zika PCR remained positive up to day 30 for 26.7% of patients as compared to 13.3% for urine Zika PCR. Authors also concluded that whole-blood Zika PCR was more sensitive than serum or urine Zika PCR as whole-blood Zika PCR had the highest positivity rate of 62 out of 92 samples and was detected at up to day 120 for 3 patients.	15	0.93	0.80
da Silva et al. (2017) [99]	To investigate the percentage of acute zika infection in a cohort of patients admitted for Guillain-Barré syndrome, meningoencephalitis, or transverse myelitis.	35 of 40 patients enrolled in this study had serologic or molecular evidence for recent Zika infection.	This study reported a high incidence of rash (83%) in the patients with Zika infection.	35	0.83	0.29
Duijster et al. (2016) [100]	To investigate the epidemiological, virological, and clinical characteristics of imported Zika infection	There were 18 cases in this study, of which 17 had rash, 16 had fever, 13 had arthralgia, 8 had conjunctivitis. 13 cases had checked for dengue, and 3 of these were weakly positive for dengue IgM.	11 out of 17 patients with rash experienced pruritus. Rash could be localized or generalized.	18	0.94	0.44
Brasil et al. (2016) [101•]	To characterize the clinical, epidemiological, and virological features of Zika disease in the outbreak in Rio de Janeiro in 2015.	Zika was present in Rio de Janeiro in Jan 2015 and the number of infections peaked in May/June 2015. Common symptoms in this cohort included headache, myalgia,	97% of cases had rash, 79% had pruritus, 56% had conjunctivitis, 21% had enanthema/petechiae/bleeding, 20%	119	0.97	0.56

Table 2 (continued)

Study	Purpose of study	Primary outcomes of study	Related outcomes to our study	Number of patients	Frequency of rash	Frequency of conjunctivitis
		arthralgia, conjunctivitis, lower back pain, and itching. Study authors concluded that pruritus should be included in the case definition by Pan American Health Organization as it was the second most frequent symptom in the study.	had nasal congestion, 15% had coryza.			
Meaney-Delman et al. (2016) [102]	To highlight the range of outcomes when pregnant women become infected with zika.	This study included 9 cases, of which there were 2 early losses, 2 elective terminations, 3 live births, and 2 further continuing pregnancies at that time.	The report provided more details for 4 of the 9 cases. In all 4 cases, the pregnant women had experienced rash.	4	1.00	0.00
Hills et al. (2016) [103]	To highlight that sexual transmission of Zika is more common than previously reported.	Study described 3 cases in which female partners who had not traveled developed confirmed Zika infections. They had had sexual intercourse with male partners who had traveled and were symptomatic at the time of intercourse.	This report also shows that rash and conjunctivitis are common symptoms in Zika, being present in 83% and 67% of the cases featured here respectively.	6	0.83	0.67
Thomas et al. (2016) [104]	This report characterized the features of zika disease that occurred during the outbreak from Nov 23, 2015 to Jan 28, 2016 in Puerto Rico	The study found that 93% of patients lived in eastern Puerto Rico or the San Juan metropolitan area. 77% of patients had rash, 77% had myalgias, 73% had arthralgia, and 73% had fever.	77% of patients had rash and 27% had conjunctivitis.	30	0.77	0.27
Buathong et al. (2015) [105]	Study reported cases spread throughout Thailand to show that Zika was endemic.	Study reported cases spread throughout Thailand to show that Zika was endemic.	All 5 cases in this report had fever and maculopapular rash, while only 2 of 5 had conjunctivitis.	5	1.00	0.40

Fig. 5 Maculopapular rash in a patient with Zika virus infection

probability of Zika infection by approximately 35 to 44% [107••]. In line with the case reports reviewed above, another analysis of the same two cohorts showed conjunctivitis to be more important than rash in distinguishing zika virus infection from dengue fever. This was recently shown in a validated model [108].

Singapore is one of the few high-income countries that have experienced Zika outbreaks. The actual specific diagnosis of Zika virus infection is complicated by the high degree of cross-reactivity between the different flaviviruses. While there are commercially available serodiagnostics available for Zika virus infection, they lack specificity. PCR is much more specific but availability is limited in the predominantly resource-limited countries where Zika virus infection has occurred. The World Health Organization (WHO) and United States Centers for Diseases Control and Prevention (US CDC) case definitions of Zika virus infection both incorporate rash as one of the clinical criteria for diagnosis of Zika virus infection. As such, it is possible that rash is over-represented as a clinical manifestation in published reports or case series of Zika virus infection as cases would not be tested or diagnosed with Zika virus infection in the absence of rash in settings with relatively limited resources.

The timing of rash appearance may also help distinguish Zika versus dengue infection. Meltzer et al. retrospectively analyzed 49 cases of travelers with Zika infection and suggested that the onset of rash in Zika is usually in the first 2 days of symptoms, compared with dengue infection, where rash onset is usually at defervescence, around the fifth day of symptoms. This is consistent with our finding that the median onset of rash in individual adult patients with acute Zika infection is day 1, and mean onset is day 2 [109•].

For neonates with congenital Zika syndrome, the presence or absence of redundant scalp skin is not often highlighted in the literature. In Van der Linden et al.'s study, 3 infants with craniofacial disproportion who were normocephalic at birth had redundant scalp skin, but later progressed to develop postnatal microcephaly [17•]. Three other cases in the literature had redundant scalp skin associated with severe microcephaly. Further prospective studies are required to evaluate whether redundant scalp skin at birth in a normocephalic infant with congenital Zika syndrome can predict the development of postnatal microcephaly. There were no mucosal features reported in congenital Zika syndrome or in the single infant who had acute Zika infection via transmission through breastfeeding.

Conclusion

Zika has emerged as a major cause of morbidity particularly from the point of view of neurological complications and the congenital zika syndrome. While mucocutaneous complications are common, they are often non-specific. It is important for every clinician working in a climate where the *Aedes* spp. mosquito is prevalent to recognize the spectrum of these signs, especially as the presence of rash with conjunctivitis may guide diagnostic testing to improve the management of patients with acute febrile illnesses in particular pregnant women.

Compliance with Ethical Standards

Conflict of Interest Xuan Qi Koh, Nisha S. Chandran, Paul A. Tambyah declare that they have no conflict of interest.

Ethical Approval This article does not contain any studies with human or animal subjects performed by any of the authors.

mSphere [Internet]. 2017;2(4). https://doi.org/10.1128/mSphere.00292-17 **This paper demonstrated in vitro differences between the pathogenicity of Asian and African strains of Zika virus on central nervous progenitor cells. The authors postulated that such differences contributed to the masking of the association of Zika with congenital microcephaly due to earlier circulating African strains being more pathogenic such that fetuses did not survive to term. More research is required to investigate whether there are phenotypic differences in skin cells as well, since there are no published reports of African Zika virus infection for comparison of clinical mucocutaneous features with Asian Zika infection.**
