Abstract

Background One of the undesirable complications that might occur after breast augmentation with silicone implants is capsular contracture. In its etiology, the relations between mast cells and myofibroblasts play an important role in collagen synthesis. Mast cells are able to activate fibroblasts into myofibroblasts, through paracrine secretions, inducing collagen production. The objectives of this study were to analyze the myofibroblast concentration through the α-SMA immunomarker and evaluate the intensity of mast cell expression against the C-Kit immunomarker.

Material and Method Sixty-four Wistar rats were used, divided into two groups (polyurethane foam and textured surface) with 32 animals in each. The animals received silicone implants on the back, below the *panniculus carnosus*, and after the determined period, they were killed and the capsules formed around the implants were studied. The capsules were analyzed employing the immunohistochemical technique, with the α-SMA and C-Kit immunomarkers in subgroups of 30, 50, 70 and 90 days.

Results The myofibroblast concentration was higher in the polyurethane group when compared to the textured group (30 days $p = 0.105$; 50 days $p = 0.247$; 70 days $p = 0.014$ and 90 days $p = 0.536$). The intensity of mast cell expression was more pronounced in the polyurethane group when compared to the textured group (30 days $p = 0.798$; 50 days $p = 0.537$; 70 days $p = 0.094$ and 90 days $p = 0.536$).

Conclusions Polyurethane-coated implants induced higher concentrations of myofibroblasts and higher expression of mast cells, when compared to the textured surface implants.

Introduction

The most performed plastic surgery worldwide is breast augmentation [1]. All material introduced into the human body provokes a foreign body reaction with formation of a fibrous capsule around it [2, 3]. The capsule might become hard, causing deformity and breast pain, a condition known as capsular contracture [4–6].

Regarding its etiopathogenesis, many studies have already been carried out researching the variety of factors involved: implant coating, biofilm formation, hematoma, unsuitable surgical technique, pathological healing, among others [3, 7–17].

Nowadays, the most used types of coating in silicone implants are smooth, textured (nano, micro, intermediate and macro) and polyurethane foam [1, 18–21]. From these, the one with the lowest capsular contracture rate in breast augmentation is polyurethane foam with a 0.4–1% rate, followed by textured implants with 2–15% [19].

One of the reasons is the fact that polyurethane foam biodegradation, through hydrolysis, prevents the adhesion of fibroblasts and endothelial cells to the capsule collagenous layer, reducing the risk of contracture and extending the inflammatory reaction [12, 22].

Also, during this process, new resulting vectors are created on the surface of the silicone implant, with different lengths and directions, which justify the lower incidence of capsular contracture in this type of coating [23].

Polyurethane-coated implants, in spite of developing thicker capsules, show an increase in non-collagenous capsules, and, therefore, present lower amounts of type I collagen, when compared to textured implants [15, 22, 24, 25].

One unfavorable characteristic of the macro-textured implants and those with polyurethane foam is that they present a higher surface area, which makes them more prone to biofilm formation. In their surface grooves, the bacteria find a larger area to fix themselves. This is relevant, because the risk of developing large cell anaplastic carcinoma is 14.11 times higher with Biocell® (Allergan, Dublin, Irlanda) implants and 10.84 times higher with polyurethane implants [26].

As regards capsular contracture, the last publications on the theme emphasize the cell interrelations and their relations with inflammatory mediators. In the cell environment, studies have been developed on the factors that lead fibroblasts to transform into myofibroblasts with a smooth muscle alpha actin positive marker (α-SMA), and also how this transformation is mediated by macrophages, T cells and mast cells [3, 13, 16, 27–33].

Recently, the presence of toll-like receptor 4 in fibroblasts and myofibroblasts has been reported and correlated positively with estrogen receptors beta. These receptors, when activated, induce a pro-fibrotic state with the transformation of fibroblasts into myofibroblasts, and this process is closely related to the female hormone estradiol [16].

Receptors (AT_1R, H_1R and TGF-βRI) were also identified in fibroblasts, with expression for mediators produced by mast cells (renin, histamine and the transform growth factor beta). Another important connection between mast cells and fibroblasts is the intercellular junctional communications, which present six connexin proteins in their constitution, among which connexin 42 outstands. Thus, through paracrine secretions, mast cells are able to induce collagen production, activating fibroblasts and myofibroblasts [27, 28, 30, 33–35].

After activated, myofibroblasts become an important collagen producing source, and this might contribute to the development of capsular contracture [13, 16, 29, 32, 33, 36, 37]. In hypertrophic scars, there is a predominance of mast cells, which in a normal scar do not appear in great number [29, 35].

The objective of this study was to compare the intensity of the expression of mast cells, the myofibroblast concentrations, and to compare the capsules formed by polyurethane-coated silicone implants and those with a textured surface.

Materials and Methods

This study was carried out at the vivarium of a State University, after being approved by the Animal research ethics Committee. All experimental steps were assisted by the presence of a veterinarian.

The study comprises a double-blind randomized clinical test, in which 64 Wistar rats (*Rattus norvegicus*) weighing between 190 and 250 g, aged between 30 and 90 days, were used. The animals were distributed in 500 cm^3 acrylic boxes with four animals in each. They received free access to water and feed appropriate to the species, at room temperature and 12 h circadian cycles. They were divided into two groups with 32 animals each and called the polyurethane group and textured group. They were then subdivided into four subgroups according to the time when death occurred (30, 50, 70 and 90 days).

The silicone implants used were polyurethane foam-coated and textured surface, both donated by the company Silimed (Maximum®, Rio de Janeiro, Brazil).

Experimental Steps

The rats were anesthetized using intraperitoneal injection of 1% ketamine (40 mg/kg) and 2% xylazine (8 mg/kg).

Next, they were put in the prone position and trichotomy was performed on the back. The surgical procedure was carried out in antiseptic conditions and with sterilized silicone implants and surgical material.

The incision was performed on the back and the pocket that housed the implants was made on the retromuscular plane with scissors in a cranial direction, starting 5 mm from the incision and with a square shape. The implants were inserted and placed 5 mm from the incision. The skin suture was performed with three simple stitches using mononylon 5-0 (Fig. 1 and Video 1) (Mononylon Ethilon®, Ethicon Incorporation, New Jersey, USA).

The wound was kept exposed, and postoperative analgesia was applied with a single, intramuscular injection of dipyrone (20 mg/kg) on the outside of the hind limb [15, 38]. There were no postoperative dressings or stitch removal.

The rats were killed according to their subgroups with an application of ketamine and xylazine, corresponding to four times the therapeutic dose and subsequent cervical dislocation. Seven animals were excluded due to implant extrusion—four from the polyurethane group (2 from the 50-day, 2 from the 70-day and 1 from the 90-day subgroup) and three from the textured group (all of them from the 50-day subgroup).

The histological material was obtained upon bloc resection, from the skin to the muscular plane, with the surgical margins of the anatomical pieces 5 mm from the edge of the discoid implants (Fig. 2 and Video 2).

Immunohistochemical Evaluation

The tissue microarray technique (TMA) was employed in this research, which consists of a paraffin block holding several samples of different tissues, whose relevant areas for immunohistochemical stain were collected from several donor blocks and rearranged on a single receiving block [39, 40].

The immunohistochemical method was used with the indirect technique employing the smooth muscle alpha acting markers (α-SMA, 1:400, Dako, clone 1A4) and CD-117 antibody (C-Kit, 1:100, Dako, clone A4502). The pathologist did not know which animal group was being investigated. During the result analysis, they selected the best slides for photomicrographic documentation.

The immunomarked slides were then read, using an optical microscope (Axio Scope.A1®, Zeiss, Oberkochen, Germany), coupled to a digital camera (AxioCam MRc®, Zeiss) and a computer with image analysis software (AxioVision®, Zeiss). Images were captured in a 400 × high power field (HPF), whose total area was 144.073,3 μm^2, with a 1024 × 768 pixel resolution, for each case of the study.

A HPF image was chosen for the mask confection, showing the suitable positivity for the biomarker chosen. An image of the rats in the experiment was used rather than one from the reaction control (Fig. 3).

The mask was then overlapped to the digital images of the cases. Based on its ideal immunopositivity, the image analysis software (Image Pro-Plus®, Media Cybernetics,

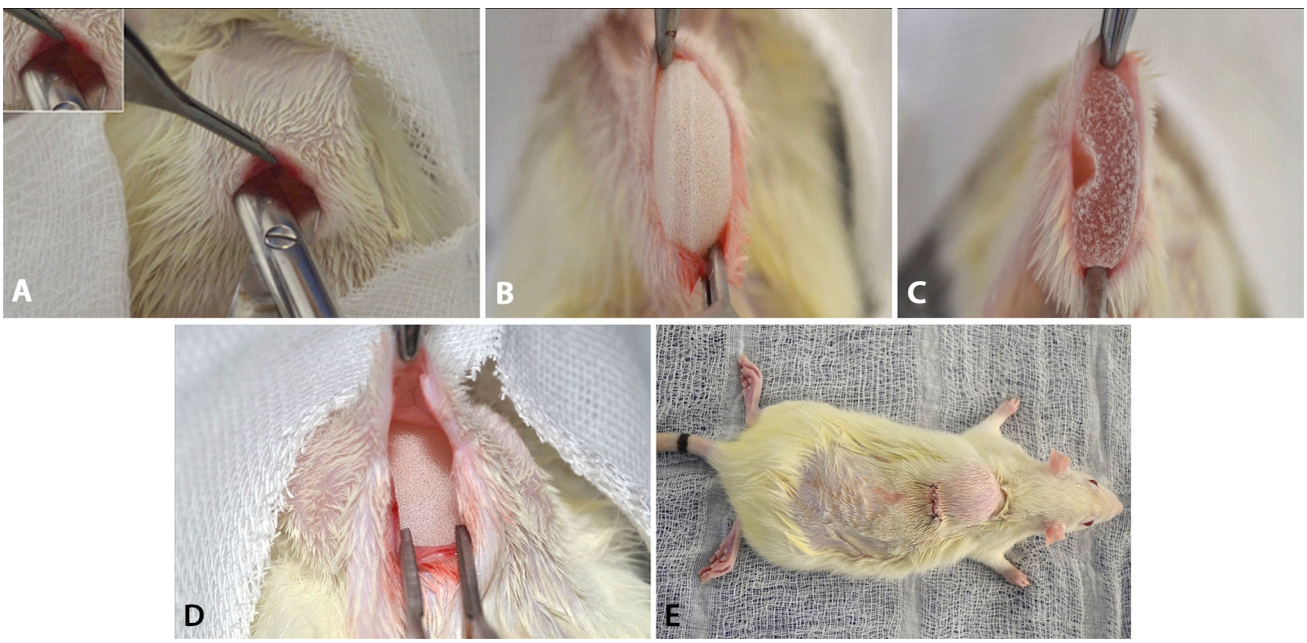

Fig. 1 **a** Pocked creation in the *panniculus carnosus* to house the implant; **b** introduction of polyurethane-coated implant; **c** introduction of the textured surface implant; **d** implant positioned 5 mm from the incision; **e** final aspect in the immediate postoperative

Fig. 2 Bloc resection of the piece for histological study

Rockville, USA) found the immunopositive areas in the samples and transformed this data into immunopositive area per square micrometer (μm^2) (Fig. 4).

The area in μm^2 generated by this method was then divided by the constant 144.073,3 μm^2, which is the total area of the field under evaluation, generating a percentage of immunopositive area through HPF. The mean percentage of area in HPF was calculated for each case.

Statistical Analysis

For the analysis presented below, the percentage of expression of the α-SMA and C-Kit immunomarkers was considered. From the results of the slide reading, data were obtained as: 100 × positive area/(positive area + negative area). This indicates that the variables under analysis (α-SMA and C-Kit) correspond to the 'positive' area mean in relation to the total 'positive' and 'negative' areas. The statistical analysis was assisted by the software IBM SPSS Statistics v.20® (International Business Machines, North Castle, USA).

Results

Immunohistochemical Markers

Smooth Muscle Alpha Actin Marker (α-SMA)

In all groups analyzed (30, 50, 70 and 90 days), the mean of the positive area percentage for the α-SMA immunomarker was higher in the polyurethane group, and in the subgroup 70 days, it was statistically significant (Table 1 and Fig. 5).

Figure 6 illustrates the differences of positive area percentages for the α-SMA immunomarker between each of the groups in the different subgroups under analysis.

Table 2 shows the "*p*" values of the results of α-SMA positivity percentages in each group, comparing all the subgroups, to verify whether a statistical difference would be found between the groups.

CD-117 Antibody Marker (C-Kit)

In all subgroups under analysis (30, 50, 70 and 90 days), the mean of positive area percentage of the C-kit immunomarker was higher in the polyurethane group, however, without statistical significance (Table 3 and Fig. 7).

Figure 8 illustrates the differences of positive area percentages for the C-Kit immunomarker between each group in the different subgroups under analysis.

Table 1 Comparison of the α-SMA percentage in both groups and in each subgroup

Subgroup	Group	α-SMA—positive area percentage						*p** value (*P* × *T*)
		n	Mean	Median	Minimum	Maximum	Standard deviation	
30	P	8	30.7	31.9	20.3	37.8	6.0	
	T	8	20.7	23.6	3.4	34.1	12.7	0.105
50	P	6	21.9	21.0	12.2	35.9	8.1	
	T	5	17.7	10.8	2.4	53.6	20.9	0.247

Table 4 presents "p" values of the results of the C-Kit positivity percentages in each group, comparing all subgroups, to verify whether a statistical difference would be found between the groups.

A significant difference was found in the textured group, between the subgroups 30, 50, 70 and 90 days, in relation to the C-Kit positive area percentage ($p = 0.017$). Thus, the groups were compared in pairs, to see which groups presented statistical significance (Table 5).

As explained above, in the textured group, when the different subgroups were compared one to the other, statistical significance was observed between the subgroups 30 and 70 days ($p = 0.004$) and between the 30 and 90 days ($p = 0{,}003$).

Discussion

The rat (*Rattus novergicus albinus*, Roentia mammalia), chosen by the author, is the most used in capsular contracture studies for presenting easy reproducibility of results, resistance to surgical intervention, high availability in vivarium, and the capsules formed around the silicone

Table 3 Comparison of the C-Kit percentages in both groups and in each subgroup

implants can be studied in these animals after a 30-day period [2, 12, 15, 22, 41–49].

The reason that polyurethane foam-coated implants and those with a textured surface were chosen is that both implants present the lowest rates of capsular contracture, which were 0.4–1% and 2–15%, respectively [19].

A close relation between fibroblasts and mast cells was seen which might lead to the pro-fibrotic condition. From the evidence that supports this fact, we highlight the identification of receivers in fibroblasts (AT_1R, H_1R and TGF-βRl) with expression for the mediators produced by the mast cells (renin, histamine and TGF-β), and the existence of intercellular junctional communications, mainly connexin 43 [35].

Recent studies involving in vitro cell culture have demonstrated that through intercellular junctional communications the mast cells influence the proliferation of fibroblasts, the contraction of the fibroblast populated collagen net, a greater transformation of fibroblasts to myofibroblasts and reduced migration of fibroblasts and that degranulated mast cells present similar behavior, due to the maintenance of these intercellular communications [27, 28].

Regarding the intercellular relation, mast cells were seen to prevent dexamethasone-induced cell death in fibroblasts cultivated in vitro. Junctional communications between the mast cells and fibroblasts prevent the apoptosis of these cells, resulting in a greater number of fibroblasts and myofibroblasts, which might be related to hypertrophic scar genesis [29].

Thus, through paracrine secretions, the mast cells are able to induce collagen production through fibroblasts [30]. The mast cell released chymase results in an increase in the TGF-β1/ SMAD intracellular signaling, resulting in proliferation of fibroblasts in hypertrophic scars and in collagen synthesis [33].

An interesting fact is that a small number of mast cells can activate a great number of fibroblasts into myofibroblasts, in a 1:10 ratio, to obtain maximum collagen synthesis [28], while in situations where inactive mast cells are activated, it results in the normalization of the number of myofibroblasts and collagen [51].

Another way of activating mast cells is through the bacteria *Staphylococcus aureus*. In an in vitro study, they

were incubated with cytochalasin D or with anti-receptor antibodies toll 2 or anti-CD 48, and their cell invasion ability and that of initiating an inflammatory response were inhibited [53].

In a study on capsular contracture in humans, the presence of mast cells around the capsules formed on silicone implants was analyzed, and a greater number of mast cells were found in the posterior capsular portion rather than in the anterior one. Baker IV capsules showed greater numbers of fibroblasts when compared to Baker I capsules [30].

An attempt to reduce collagen production upon the inhibition of mast cells has been the use of off-label anti-leukotrienes. In a study with rats with textured silicone implants which received a 5 mg/kg/day zafirlukast dose, lower numbers of mast cells were found when compared to the control group, which did not receive this medication [43].

The present study is the first in the literature to evaluate the presence of mast cells quantitatively. In both groups, in all subgroups under evaluation, myofibroblasts were evidenced by α-SMA, always concomitantly to mast cells, visualized by the use of the C-Kit immunomarker.

With results slightly different than the ones in this study, Bui et al. [50] reported the absence of positive α-SMA immunoreactivity in all capsules formed around textured implants. However, it seems relevant to emphasize that those authors researched humans, and this research was developed with rats.

In a recent publication, Silva et al. [15] compared histologically the capsules formed by polyurethane foam implants and those with textured surface. They found a result similar to the result of this study, with the polyurethane group, in all subgroups under evaluation, presenting higher numbers of myofibroblasts, when compared to the textured group.

Similarly to Vieira et al. [22], the animals in the polyurethane group showed more pronounced expression of the α-SMA marker in all subgroups under evaluation when compared to the textured group. The difference between the studies is the fact those authors obtained statistical significance in the subgroup 30 days, whereas in this study, the results were statistically significant in the subgroup 70 days.

Unlike Hwang et al. [52], who stated that there was no influence of the implant coating in the number of myofibroblasts, in this study, the polyurethane foam implants presented higher numbers of fibroblasts. However, those authors compared textured and smooth implants, in humans, while in this study, polyurethane and textured surface implants in rats were compared.

The results of this study do not agree with those found by Younan et al. [9], who reported higher collagen maturation upon activation of mast cells through microdeformational wound therapy (vacuum assisted closure); in this study in both groups in all subgroups under evaluation, mast cells were found in an inversely proportional relation with the period of analysis. That is, the later the period under analysis was, the lower the number of mast cells was.

These data are also in agreement with Silva et al. [15], who found in the relation time dependence, higher amounts of mature collagen (type I) and lower amounts of immature collagen (Type III), in groups with polyurethane and textured implants, in all subgroups.

Conclusion

Polyurethane foam-coated silicone implants induced higher concentrations of fibroblasts and a higher intensity of mast cell expression, when compared to textured surface implants. In relation to the area percentage expressed by mast cells, statistical difference was found in the textured group between the different subgroups under analysis, and when the groups were compared one to another, there was statistical significance between 30 and 70 days and 30 and 90 days.
