Statins

Cardiac catheterization

ABSTRACT

Background: The optimal preventive strategy for contrast induced acute kidney injury (CIAKI) in patients undergoing cardiac catheterization remains uncertain.

Objective: We conducted Bayesian network meta-analysis (NMA) to compare different preventive strategies for CIAKI in these cohorts.

Methods: Forty-nine randomized controlled trials were extracted using MEDLINE, EMBASE and CENTRAL data bases (inception–1st December 2017). We calculated median of the odds ratio (OR) with the corresponding 95% credible interval (CrI). The ranking probability of each treatment was based on SUCRA (surface under the cumulative ranking curve).

Results: In NMA of 28,063 patients [normal saline (NS: 9716 patients), sodium bicarbonate (NaHCO₃: 4484 patients), statin (2542 patients), N-acetylcysteine (NAC: 3006 patients), NAC + NaHCO₃ (774 patients), NS + NAC (3807 patients), NS + NaHCO₃ (135 patients) and placebo (3599 patients)], statins reduced the relative risk of CIAKI compared with NS (OR: 0.50; 95% CrI, 0.25–0.99), and placebo (OR: 0.44; 95% CrI, 0.24–0.83). Sub-group analyses showed that in patients receiving low osmolar contrast, statins reduced the relative risk of CIAKI by 58% versus NS, and 51% versus placebo. There were no significant differences across all the treatments in terms of risk of hemodialysis or all-cause mortality. Statins had the highest probability for reducing the risk of CIAKI (SUCRA, 0.86), risk of hemodialysis (SUCRA, 0.88) and all-cause mortality (SUCRA, 0.81).

Conclusion: Statins were the superior preventive strategy for reducing the risk of CIAKI compared with NS alone and placebo.

1. Introduction

Over the last few decades, the rise in cardiac catheterization procedures has resulted in an increased incidence of contrast induced acute kidney injury (CIAKI) and subsequently enhanced the risk of renal replacement therapy, prolonged duration of hospital stay, increased cost of care and mortality [1]. This issue has generated enthusiasm among the medical professionals to investigate the optimal therapy for prevention of CIAKI. However, due to significant heterogeneity across the published literature, the best preventive strategy for CIAKI remains uncertain. Intravascular volume expansion is considered standard of

care for prevention of CIAKI [2, 3], but the contemporary AMACING trial (Prophylactic Hydration to Protect Renal Function from Intravascular Iodinated Contrast Material in Patients at High Risk of Contrast Induced Nephropathy) has challenged this notion and demonstrated that absence of prophylactic hydration did not increase the risk of CIAKI, hemodialysis or death compared with prophylactic hydration [4]. Similarly, in the more recent PRESERVE trial (Prevention of Serious Adverse Events Following Angiography), there was no benefit of intravenous sodium bicarbonate (NaHCO₃) over normal saline (NS) or of oral N-acetylcysteine (NAC) over placebo in terms of mortality, need for dialysis or CIAKI in patients undergoing coronary angiography [5]. Due to this controversy, we performed Bayesian network meta-analysis (NMA) to compare all relevant treatment approaches employed in current clinical practice to prevent CIAKI after cardiac catheterization [6].

2. Methods

This NMA is performed and reported in compliance with the Cochrane Collaboration guidelines [7] and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) Extension statement for systematic reviews incorporating network meta-analyses for health care interventions [8].

2.1. Search strategy

Two authors (HR, MUK) conducted the electronic data base search using MEDLINE, EMBASE and CENTRAL (Cochrane Central Register of Controlled Trials) from inception to 1st December 2017. Following search terms were used to generate search algorithm: “contrast induced nephropathy”, “CIN”, “acute kidney injury”, “AKI”, “contrast induced acute kidney injury” “acute renal failure”, “ARF”, “coronary angiography”, “cardiac catheterization”, “angioplasty”, “percutaneous coronary interventions” and “PCI”. We also reviewed online libraries of www.clinicaltrials.gov, www.clinicaltrialsregister.eu, www.clinicaltrialresults.gov, www.acc.org, www.esccardio.org, www.tctmd.com, and bibliographies of the relevant articles. The search was restricted to randomized controlled trials (RCTs), full text articles and human subjects. There was no restriction on language and publication year. All the results were downloaded to Endnote X7 (Thompson ISI ResearchSoft, Philadelphia, Pennsylvania, USA) and duplicates were identified and removed manually and via EndNote.

2.2. Study selection

The pre-defined inclusion criteria were: [1] RCTs which had compared two or more preventive strategies for CIAKI in adults patients (age ≥ 18 years) undergoing diagnostic or interventional cardiac catheterization, [2] studies which reported at least one clinical event for CIAKI, [3] studies with sample size of at least 100 patients (to avoid small study effects), and [4] full text articles. We excluded observational studies and trials assessing strategies that are not widely practiced and have limited clinical applicability (xanthine, ascorbic acid, dopaminergic drugs, natriuretic peptide and peripheral ischemic preconditioning). Similarly, we also excluded trials which have compared protocol based hydration strategies rather than comparing two different treatment arms for prevention of CIN. The POSEIDON (Prevention of Contrast Renal Injury with Different Hydration Strategies) trial compared left ventricular end diastolic pressure (LVEDP) guided hydration strategy versus standard hydration. Based on a priori exclusion criteria, this trial was not selected for final analysis [9]. There were no restrictions on comorbidities or follow up duration. Study screening was done by two authors (HR and MUK) and any conflicts were resolved by consulting third author (SUK).

2.3. Data extraction and quality assessment

Two authors (MUK and HR) independently abstracted data on study, baseline characteristics of the participants, co-morbidities, number of events, and number of patients at risk, sample size, data adjudication time and follow-up duration on a pre-specified data collection form. When available, we extracted data based on intention to treat principle. Any divergence was resolved by referring back to the original article, and/or opinion of third reviewer (SUK). The primary endpoint was CIAKI. The secondary outcomes were risk of hemodialysis and all-cause mortality. A notable number of studies did not report risk of hemodialysis or all-cause mortality leading to a relatively lesser number of comparisons for secondary endpoints' analyses. In accordance with a prior NMA [10], we defined CIAKI as a relative increase of $\geq 25\%$ or an absolute increase of ≥ 0.5 mg/dL in serum creatinine within 48–72 h

after the procedure. The risk of bias of individual studies was assessed using Cochrane bias risk assessment tool [11] (Supplement (S) Table 1).

2.4. Statistical analysis

The Bayesian NMA was conducted using NetMetaXL 1.6.1 (Canadian Agency for Drugs and Technologies in Health; Ottawa, Canada) and winBUGS 1.4.3 (MRC Biostatistics Unit; Cambridge, United Kingdom). Since we made no assumptions regarding the efficacy of these treatments from data outside the included trials, random effects vague priors' model was used to estimate the posterior distribution of all parameters. For all outcomes, convergence was achieved at 40,000 iterations and auto correlation was checked and confirmed. The convergence was assessed using the Brooks-Gelman-Rubin method and by checking whether the MCMC error is $< 5\%$ of the standard deviation of the effect estimates and between-study variance [12]. The median of the posterior distribution was reported as odds ratio (OR) with the corresponding 95% credible interval (CrI) ranging from 2.5th to the 97.5th centiles of the distribution. The between-study variance was interpreted as low ($\tau^2 = 0.04$), moderate ($\tau^2 = 0.14$) and high ($\tau^2 = 0.40$) [13].

Markov chain Monte Carlo (MCMC) modeling was used to estimate the relative ranking probability of each treatment group based on SUCRA (surface under the cumulative ranking curve) [14, 15]. A SUCRA is a numerical representation of the probability of safety or efficacy of the treatment i.e. higher values represent better efficacy or safety of the treatment. Prespecified subgroup analyses were conducted to assess the effects of the treatments based on osmolarity of the contrast and setting of cardiac catheterization (emergent or elective procedure). The comparisons are shown in the form of league tables with OR < 1 means the treatment in the top left is more effective at reducing the incidence of CIN compared with rest of the treatments.

3. Results

This initial search yielded a total of 3423 records. Out of which 1902 citations were duplicates, and 865 studies were excluded at title and abstract level. Further 607 articles were removed at full text screening based on predefined inclusion/exclusion criteria. Ultimately, 49 RCTs were included in final analysis (Fig. 1). A total of 28,063 patients [NS (9716 patients), NaHCO₃ (4484 patients), Statin (2542 patients), NAC (3006 patients), NAC + NaHCO₃ (774 patients), NS + NAC (3807 patients), NS + NaHCO₃ (135 patients) and placebo (3599 patients)] were included in this NMA. The mean age of the study population was 67 ± 5 years, 69% were men, 68% had hypertension and 49% had diabetes mellitus. Baseline serum creatinine was 1.3 ± 0.3 mg/dL. The endpoint adjudication time varied from 24 h to 240 h (Table 1).

The NMA showed that statins were associated with 50% relative risk reduction of CIAKI compared with NS alone (OR: 0.50; 95% CrI, 0.25–0.99), and 56% risk reduction compared with placebo (OR: 0.44; 95% CrI, 0.24–0.83). There were no statistical differences among rest of the treatment strategies. The MCMC modeling suggested that statins had the highest probability of having the lowest rate of CIAKI (SUCRA, 0.86), followed by NAC (SUCRA, 0.75), NaHCO₃ + NAC (SUCRA, 0.64), NaHCO₃ (SUCRA, 0.54), NS + NAC (SUCRA, 0.45), NS + NaHCO₃ (SUCRA, 0.29) and NS (SUCRA, 0.25) (Fig. 2).

The NMA did not demonstrate statistical differences between statins, NS, NAC, NS + NAC, NaHCO₃, NaHCO₃ + NAC or placebo with regards to risk of hemodialysis (Fig. 3). In the probability analysis, the MCMC modeling suggested that statins had the highest probability of having lowest risk of hemodialysis (SUCRA, 0.88), followed by NS (SUCRA, 0.60) and NAC (SUCRA, 0.59) (Fig. 3). The NMA also failed to demonstrate significant differences in terms of all-cause mortality among statins, NaHCO₃, NAC, NS, NS + NAC, NaHCO₃ + NAC and placebo. The MCMC modeling suggested that statins had the highest probability of reducing all-cause mortality (SUCRA, 0.81), followed by

NaHCO₃ (SUCRA, 0.72) (Fig. 4). There was a higher degree of statistical heterogeneity for CIAKI ($\tau^2 = 0.66$), while risk of hemodialysis and all-cause mortality were affected by moderate ($\tau^2 = 0.21$) and low degree of heterogeneity ($\tau^2 = 0.08$) respectively.

Subgroup analyses showed that when low osmolarity contrast was used for cardiac catheterization, statins were superior to NS alone (OR: 0.42; 95% CrI, 0.20–0.82) and placebo (OR: 0.41; 95% CrI, 0.23–0.74) in reducing the risk of CIAKI. The MCMC modeling showed that statins had the highest probability of reducing the risk of CIAKI in patients having low osmolarity contrast (SUCRA, 0.97) (S Fig. 1). The NMA did not show significant differences among the treatments in patients with iso-osmolarity contrast based procedures. The MCMC modeling demonstrated that NaHCO₃ + NAC had the highest probability of being the best strategy to prevent CIAKI (SUCRA, 0.78), followed by NAC (SUCRA, 0.77) and statins (SUCRA, 0.64) (S Fig. 2).

In subgroups having elective cardiac catheterization, the NMA showed that risk of CIAKI was identical between all the treatments. The MCMC demonstrated that NaHCO₃ had the highest probability of

having the lowest risk of CIAKI (SUCRA, 0.80), followed by NAC (SUCRA, 0.66) and NaHCO₃ + NAC (SUCRA, 0.61) (S Fig. 3). In patients undergoing emergent catheterization, the NMA showed that statins reduced the risk of CIAKI by 56% compared with placebo (OR: 0.42; 95% CrI, 0.210–0.87). The MCMC modeling demonstrated that statins had the highest probability of having the lowest rate of CIAKI in the setting of emergent cardiac catheterization (SUCRA, 0.88), followed by NAC (SUCRA, 0.74) and NaHCO₃ + NAC (SUCRA, 0.56) (S Fig. 4).

4. Discussion

In this NMA of 49 RCTs including 28,063 patients, statins significantly reduced the relative risk of CIAKI compared with NS alone and placebo. These benefits were mainly driven by effects of statins in patients who received low osmolar contrast and patients who underwent emergent cardiac catheterization. There were no statistical differences between other treatments regarding the risk of CIAKI. In terms of risk of hemodialysis or all-cause mortality, all the treatment strategies

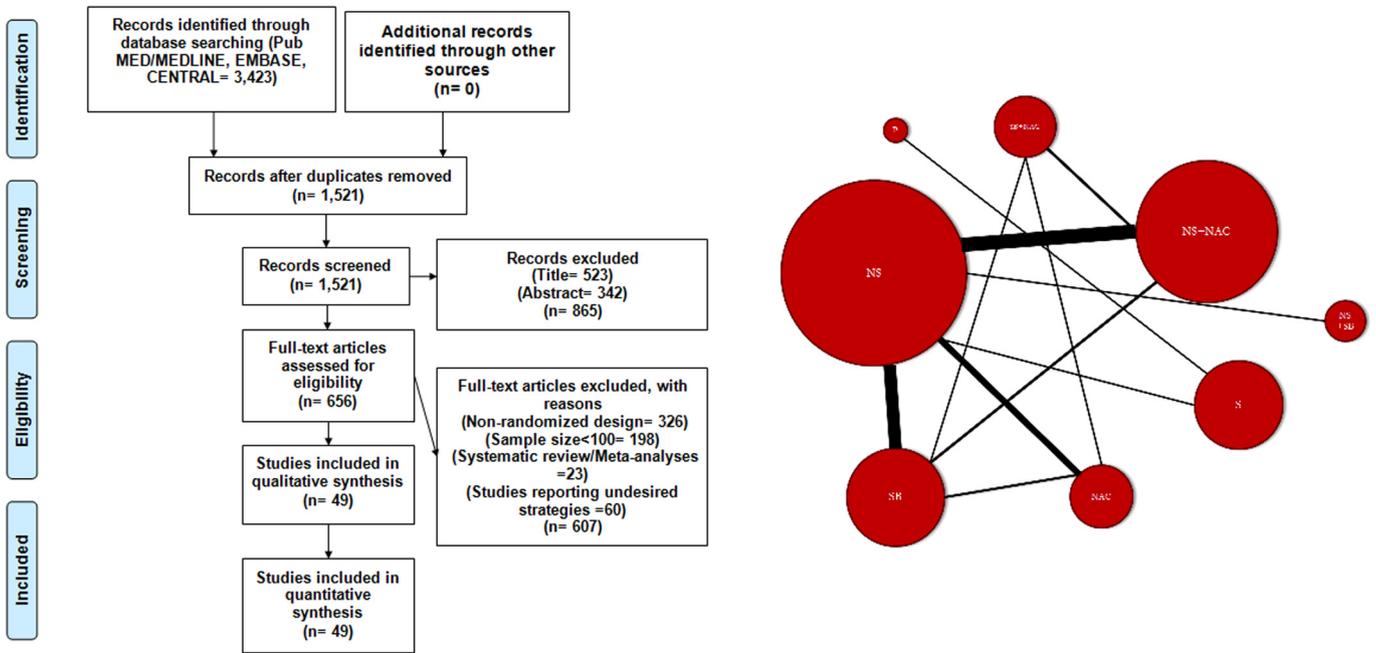

Fig. 1. Search strategy using PRISMA statement and network diagram. The size of circle represents sample size of the group. NS = Normal Saline, SB = Sodium Bicarbonate, NAC = N-Acetylcysteine, S = Statins, P = Placebo.

showed comparable outcomes. The MCMC modeling showed that statins had the highest probability of having the lowest risk of CIAKI, risk of hemodialysis and all-cause mortality.

The majority of meta-analyses on this topic were conducted via traditional methodology and compared one form of prophylaxis to other [16–18]. We are aware of at least one NMA by Giacompo and colleagues, which had utilized the Bayesian approach to compare multiple interventions [10]. Giacompo and colleagues reported that statin administration was associated with significant and sustained relative risk reduction compared with NS in patients undergoing PCI across various sensitivity analyses [10]. They further showed that xanthine, NAC, NaHCO₃, NAC + NaHCO₃, ischemic preconditioning and natriuretic

peptide might have protective effects but the results were not consistent across sensitivity analyses. But in diabetic patients, none of the interventions reduced the risk of CIAKI. This NMA had certain short-coming. First, this study assessed treatments which are not used in routine clinical practice (ascorbic acid, xanthine, dopaminergic agent, peripheral ischemic preconditioning and natriuretic peptide), and hence had relatively limited clinical applicability of the provided evidence. Second, the NMA focused only on CIAKI and did not assess the risk of hemodialysis or all-cause mortality, which represent more serious sequelae of contrast related renal complications. Third, due to inclusion of studies with small sample size, this NMA was potentially affected by reporting bias due to small study effects [19]. Finally, this NMA

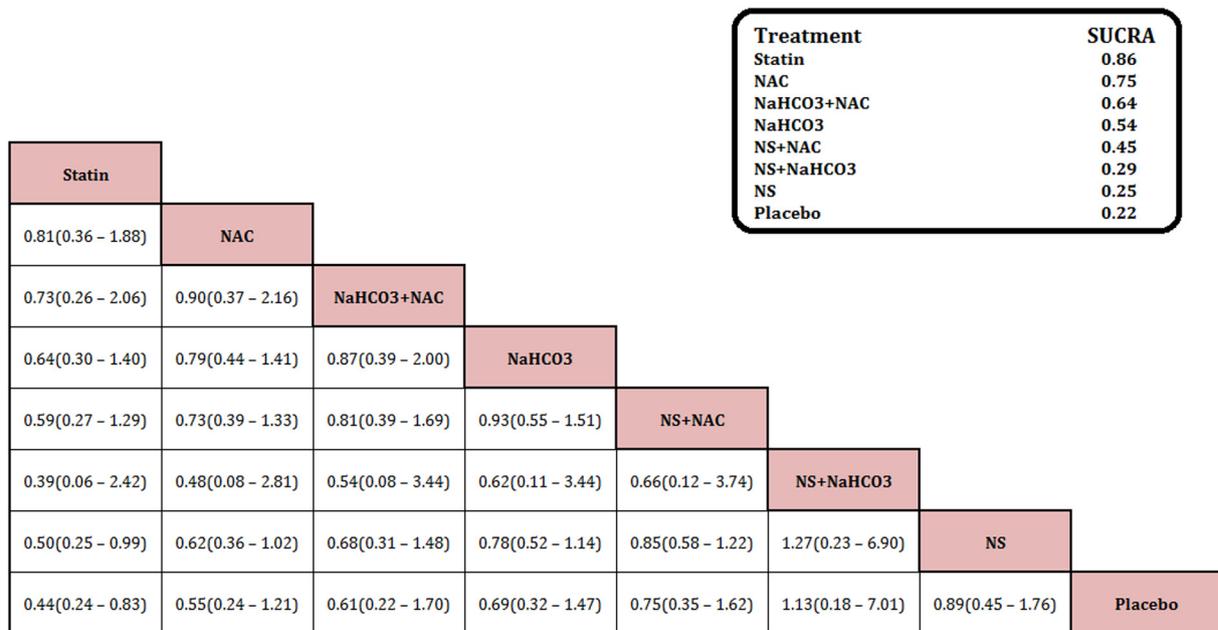

Fig. 2. League table comparing different treatment strategies for CIAKI. OR < 1 means the treatment in the top left is more effective than other interventions. NAC = N-Acetylcysteine, NaHCO₃ = sodium bicarbonate, NS = Normal Saline.

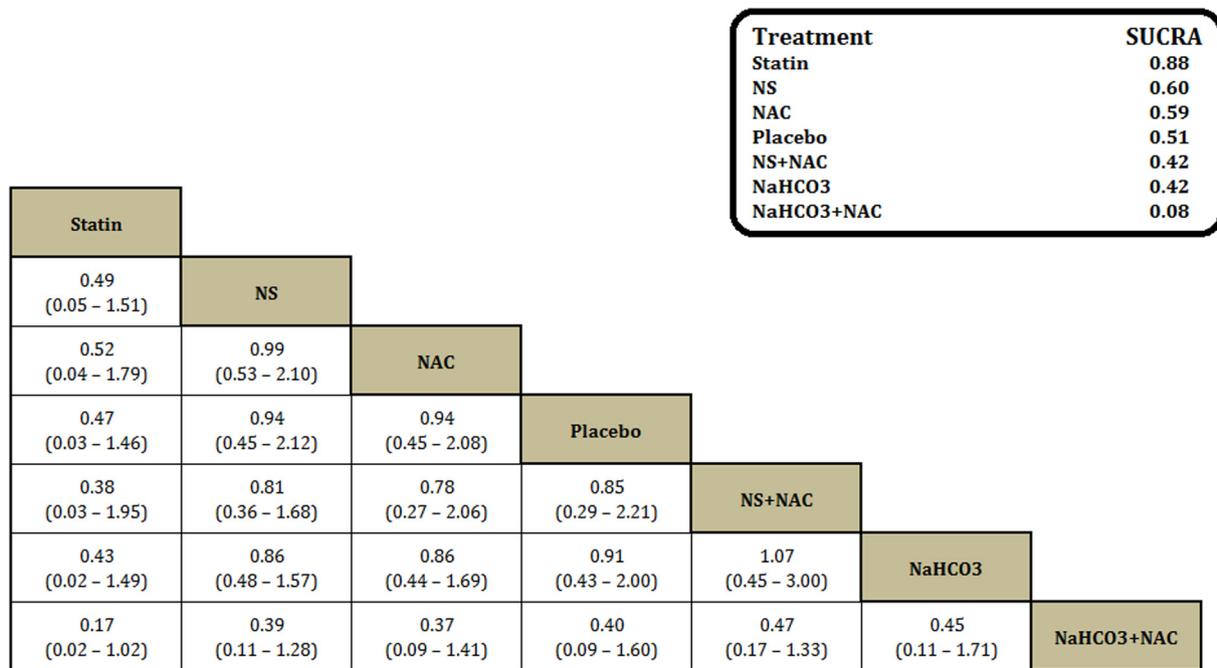

Fig. 3. League table comparing different treatment strategies for risk of hemodialysis. OR < 1 means the treatment in the top left is more effective than other interventions. NAC = N-Acetylcysteine, NaHCO3 = sodium bicarbonate, NS = Normal Saline.

was published prior to AMACING [4] and PRESERVE [5] trials and thus lacked these contemporary data sets. Our up to date report has encountered these limitations via a strict inclusion/exclusion criteria which allowed us to include studies with relatively larger sample size, compare relevant treatment strategies and generate comprehensive assessment of contrast associated renal complications and mortality.

In another meta-analysis of 125 trials including >6000 patients, Sayegh et al., showed that statins reduced the risk of CIAKI by 55% compared with placebo (OR, 0.45, 95% confidence interval, 0.35–0.57) [20].

Meta-analysis by Subramaniam and colleagues included 86 RCTs comparing NAC, NaHCO3, statins, ascorbic acid and NS [21]. This study showed that low dose NAC plus NS and NAC plus NS significantly reduced the relative risk of CIN compared with NS alone. Moreover, greatest reduction in CIN was observed with NAC plus NS in patients receiving low osmolar contrast and with statins plus NAC plus NS. This was a pair-wise meta-analysis which essentially validates the impression that NS alone was not an optimal approach for prevention of CIN and groups receiving statins had significant benefit compared with

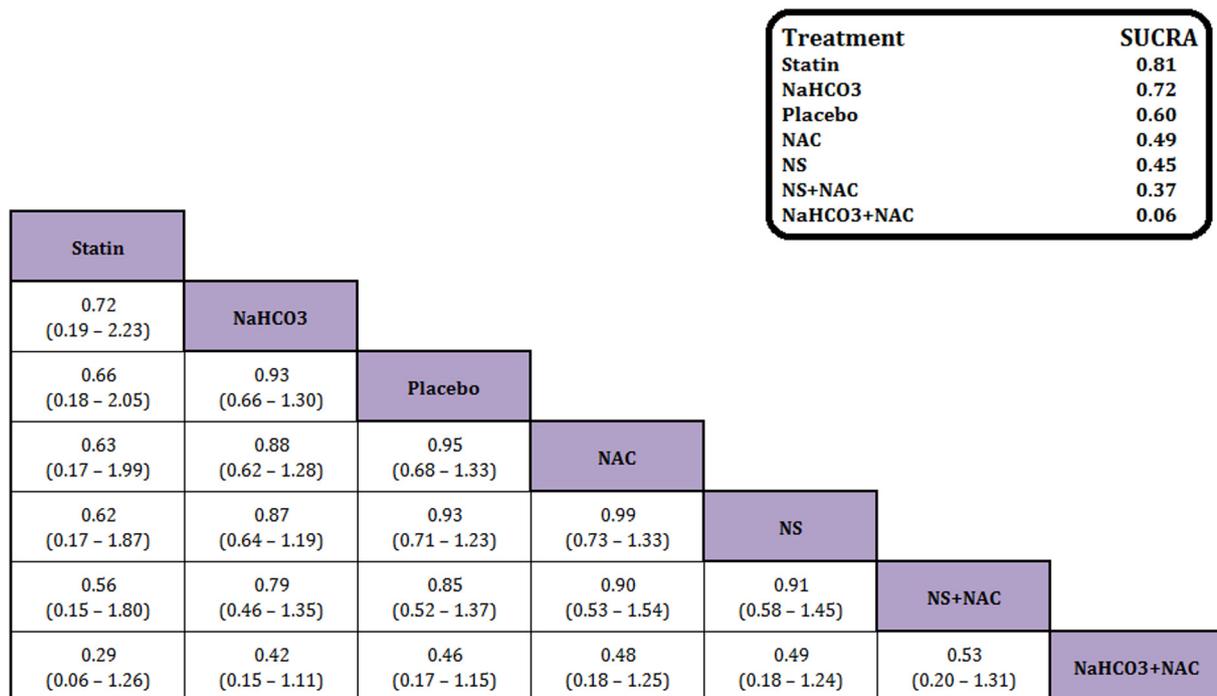

Fig. 4. League table comparing different treatment strategies for risk of all-cause mortality. OR < 1 means the treatment in the top left is more effective than other interventions. NAC = N-Acetylcysteine, NaHCO3 = sodium bicarbonate, NS = Normal Saline.

groups without statins. Furthermore, interventions had more benefit in patients who received low osmolar contrast versus iso-osmolar contrast. However, because this study did not utilize Bayesian principles and therefore probability analyses could not be conducted. Our report can be considered an extension of these findings which ranked the treatments based on their efficacy suggesting that statins were most effective intervention followed by NAC while NS alone was ranked just above placebo on rankogram.

Theoretically, statins due to their “pleiotropic effects” can improve endothelial function, stabilize the atherosclerotic plaques and subsequently mitigate oxidative stress [22]. Statins can be highly effective in the state of profound inflammation and ultimately impede the process of contrast induced tubular cells apoptosis [23]. Perhaps, this is the reason that statins were more effective in emergent cardiac catheterization, which is a state of high inflammatory response.

There is significant body of evidence suggesting periprocedural hydration for the prevention of CIAKI in patients undergoing PCI [24, 25]. In recent PRESERVE trial, periprocedural intravenous NaHCO₃ showed no benefit over NS in terms of risk of CIAKI or mortality. Moreover, there was no benefit of using oral NAC over placebo with respect to the risk of renal complications in patients undergoing angiography. These findings suggest that use of NaHCO₃ or NAC can no longer be recommended in high risk patients receiving angiography and IV hydration with NS remains the mainstay of the prevention of CIN [5]. Conversely, a more recent meta-analysis (61 RCTs, 11,480 patients) suggested that in patients undergoing coronary angiography, use of NAC was associated with 26% relative risk reduction compared with control (RR, 0.74; P = 0.0002) [26]. On the same note, the AMACING trial suggested that withholding hydration in patients with eGFR > 29 mL/min/1.73 m² might be a safer approach in patients receiving contrast media [4]. It is important to note that ~48% patients receiving intra-arterial contrast underwent contrast enhanced computed tomography while only ~16% patients received coronary angiography or PCI in this study. Current NMA attempted to incorporate available quality data to provide a comprehensive summary of the evidence for prevention of CIN which is consistent with various former reports [10, 20, 21].

Our NMA has certain limitations. First, this study was conducted on study level information and due to lack of individual patient level data; various important subgroup analyses (age, comorbidities, contrast volume, baseline eGFR or CrCl etc.) could not be performed. Second, like former meta-analyses, there was a noticeable heterogeneity across the studies with respect to methodology, dosing of the treatments, contrast agents, their strength and volume, procedural setting, definition of CIAKI, adjudication timing of renal function and characteristics of the patients. Similarly, use of background volume expansion with concomitant use of oral NAC in certain studies might have generated a potential bias in the treatment effect. It is also possible that in statin trials, the population without statins could be sicker than patients in statin group. These differences could potentially bias the results in favor of statins arm. These variations resulted in high degree of statistical heterogeneity for the primary estimate. However, we used random effects model to account for any between study variability. Finally, since Bayesian approach generates evidence based on direct and indirect comparison, our NMA should be viewed as hypothesis generating.

In conclusion, our NMA suggests that in patients undergoing cardiac catheterization, statins were found to reduce the risk of CIAKI compared with NS alone. The use of NS, NaHCO₃, NAC or combination of these agents provided no statistical differences in preventing CIAKI. Statins were shown to be more effective in patients receiving low osmolar contrast or requiring emergent cardiac catheterization. Neither of the strategies had significant superior protective effects on dialysis or all-cause mortality. However, probability analysis demonstrated that in addition to preventing CIAKI, statins had the highest probability of reducing the risk of dialysis and all-cause mortality. These findings do not contradict the role of background NS infusion rather suggest that a preventive strategy based only on NS infusion might not be highly effective.

These observations carry important clinical value and should be further evaluated by conducting well-powered RCTs.
